

# A SURPRISING POWER LAW RELATIONSHIP PREDICTS TRENDS IN THE TEST ACCURACY FOR VERY DEEP NEURAL NETWORKS

**Anonymous authors**

Paper under double-blind review

## ABSTRACT

Given two or more Deep Neural Networks (DNNs) with similar architectures, and trained on the same dataset, but trained with different solvers, hyper-parameters, regularization, etc., can we predict which DNN will have the best test accuracy, without peeking at the test data? Solving this question of generalization would have both theoretical impact and great practical importance. In this paper, we show how to use our new theory of Implicit (Heavy Tailed) Self-Regularization for modern Deep Neural Networks to answer this. We examine over 50 different, pre-trained DNNs ranging over 15 different architectures, trained on ImageNet, with differing test accuracies. We show that, across each architecture (VGG16, VGG19, InceptionV3/V4, ...), the reported test accuracies for each DNN are well correlated with the weighted average of the layer power law exponents. Moreover, we prove that this average complexity can be expressed simply as the average log of the Frobenius norm of the layer weight matrices. Our approach requires no changes to the underlying DNN, and does not even require access to the ImageNet data. We present and review these empirical results, and compare and contrast with recent approaches to estimate test performance of DNNs using product norms.

## 1 INTRODUCTION

## 2 THEORY OF HEAVY TAILED SELF REGULARIZATION

Let us write the Energy Landscape (or optimization function) for a typical DNN with  $L$  layers, with activation functions  $h_l(\cdot)$ , and with weight matrices and biases  $\mathbf{W}_l$  and  $\mathbf{b}_l$ , as follows:

$$E_{DNN} = h_L(\mathbf{W}_L \times h_{L-1}(\mathbf{W}_{L-1} \times h_{L-2}(\cdots) + \mathbf{b}_{L-1}) + \mathbf{b}_L). \quad (1)$$

We imagine training this model on some labeled data  $\{d_i, y_i\} \in \mathcal{D}$ , using Backprop, by minimizing the loss  $\mathcal{L}$ . For simplicity, we do not indicate the structural details of the layers (e.g., Dense or not, Convolutions or not, Residual/Skip Connections, etc.). Each layer is defined by one or more weight matrices  $\mathbf{W}_L$ , or tensors.

In this study, we only need to consider Linear and 2D Convolutional (Conv2D) layers. For the Linear layers, each  $\mathbf{W}_L$  is a single  $(N \times M)$  (real valued) 2D matrix, where  $N \geq M$ . These include Dense or Fully Connected (FC) layers, as well as 1D Convolutional (Conv1D) layers, Attention matrices, etc. For the Conv2D layers, with a  $c \times d$  kernel,  $\mathbf{W}_L$  is a 4-index Tensor, of the form  $(N \times M \times c \times d)$ , consisting of  $c \times d$  2D feature maps of shape  $(N \times M)$ . So each Linear layer  $l$  gives  $n = 1$  2D matrix  $\mathbf{W}_l$ , and each Conv2D layer  $l$  gives  $n = c \times d$  2D matrices  $\mathbf{W}_{l,i}$ . A typical modern DNN may have anywhere between 5 and 500 2D  $\mathbf{W}_{l,i}$  layer matrices.

**Heavy Tailed Universality** For any layer weight matrix  $\mathbf{W}$ , we construct the associated  $M \times M$  (uncentered) correlation matrix

$$\mathbf{X} = \frac{1}{N} \mathbf{W}^T \mathbf{W}, \quad (2)$$

and form the eigenvalue spectrum of  $\mathbf{X}$ ,

$$\mathbf{X} \mathbf{v}_i = \lambda_i \mathbf{v}_i$$

(where we have dropped the  $l, i$  indices).

We call the density of eigenvalues  $\rho(\lambda)$  the Empirical Spectral Density (ESD).

Small Neural Networks [charlesG: complete]

The layer matrices in all large, modern DNNs, do not have a scale cut-off, and, instead display scale-invariance. For any modern DNN, the ESD of nearly every  $\mathbf{W}$  layer matrix can be fit to a power law,

$$\rho(\lambda) \sim \lambda^{-\alpha}$$

which is valid within a bounded range of eigenvalues  $\lambda \in [\lambda_{min}, \lambda_{max}]$ .

The power law exponent  $\alpha$  lies, 80 – 90% of the time, in a Universal range between 2 and 4,  $\alpha \in [2, 4]$ . We have verified this empirical Universality on empirical result on over 10,000 layer matrices  $\mathbf{W}$  spanning over 50 pre-trained DNNs. Of course, there are exceptions, and in any real DNN,  $\alpha$  may range anywhere from  $\sim 1.5$  to 10 or higher.

The power law exponent  $\alpha$  is a complexity metric for a weight matrix; it describes how well that matrix encodes the complex correlations in the training data. So a natural complexity metric for a DNN is to take a weighted average of the power law exponents  $\alpha_{l,i}$  for each layer weight matrix  $\mathbf{W}_{l,i}$ .

$$\hat{\alpha} := \frac{1}{n} \sum_{l,i} b_{l,i} \alpha_{l,i}$$

The smaller  $\hat{\alpha}$ , the better we expect the DNN to represent the training data. And, presumably, the better the DNN will generalize. The only question is, what are good weights  $b_{l,i}$ ?

It turns out, we can derive the weighted average  $\hat{\alpha}$  directly from the more familiar Product Norm.

[charlesG: THE REST OF THIS SECTION is to justify this complexity metric, using the product norm for DNNs. I have sketched out some of the math,. It just needs to be presented clearly AND TO JUSTIFY computing the average log Norm (which is much faster, much simpler)]

[charles: Maybe should can state a theorem and prove it.]

**THEOREM:** *The data dependent VC-like complexity of a Deep Neural Network can be expressed a weighted average the of power law exponents describing the empirical spectral density of the layer weight matrices*

[charles:

**PROOF:...** ]

**Product Norm Measures of Complexity** Recently it has been suggested that the complexity of a DNN,  $\mathcal{C}$ , can be defined by something akin to a data dependent VC complexity, the product of norms of the layer weight matrices

$$\mathcal{C} \sim \|\mathbf{W}_1\| \times \|\mathbf{W}_2\| \cdots \|\mathbf{W}_L\|$$

where  $\|\mathbf{W}\|$  may be the Frobenius norm or even the L1-norm. (Here we can use either  $\|\mathbf{W}\|$  or  $\|\mathbf{W}\|^2$  for our complexity metric, which will make more sense below.

To that end, we consider a log complexity

$$\log \mathcal{C} \sim \log \left[ \|\mathbf{W}_1\| \times \|\mathbf{W}_2\| \cdots \|\mathbf{W}_L\| \right]$$

$$\sim \left[ \log \|\mathbf{W}_1\| + \log \|\mathbf{W}_2\| \cdots \log \|\mathbf{W}_L\| \right]$$

We define the average log norm of the weight matrices as

$$\langle \log \|\mathbf{W}\|_F \rangle = \frac{1}{L} \sum_{i=1}^L \log_{10} \|\mathbf{W}_i\|$$

which we explicitly define in terms of the base-10 log.

**Relation to Heavy Tailed Universality** We note the log matrix norm squared (and dropping the  $l, i$  subscripts) is just twice the log norm

$$\log \|\mathbf{W}\|_F^2 = 2 \log \|\mathbf{W}\|$$

which makes the following analysis much simpler.

the squared Frobenius norm is just the Trace of  $\mathbf{W}^T \mathbf{W}$ :

$$\|\mathbf{W}\|_F^2 = \text{Tr}[\mathbf{W}^T \mathbf{W}]$$

or  $N$  times the Trace of  $\mathbf{X}$

$$= \text{Tr}[N\mathbf{X}] = N \sum_{i=1}^M \lambda_i$$

For very large matrices, with many eigenvalues, we can approximate the Trace as an integral over the empirical density

[charles: We may be missing the  $N$  term here:

$$\|\mathbf{W}_{l,i}\|_F^2 \sim \int_{x_{min}}^{x_{max}} \lambda \rho_{l,i}(\lambda) d\lambda$$

Technically, the power only describes the tail of the ESD, for the range  $\lambda \in [\lambda_{min}, \lambda_{max}]$ . But for most DNN layer matrices, this range covers most the ESD. So this should also be a pretty good approximation.

Of course, we need to normalize the ESD  $\rho(\lambda)$ . For now, we simply take

$$\rho(\lambda) := (\alpha - 1) \lambda^{-\alpha}$$

so that

$$\int_0^\infty \rho(\lambda) d\lambda = 1$$

]

[michael: something like this ? Trying to figure out how to get rid of the - sign on alpha .. see end of paper

$$\int_0^\infty \rho(\lambda) d\lambda = N$$

but we really want

$$K \int_0^{\lambda_{max}} \rho(\lambda) d\lambda = N$$

See the end of this section for ideas ]

Notice we ignore that we actually want to normalize only the bounded support  $\int_{\lambda_{min}}^{\lambda_{max}} \rho(\lambda) d\lambda$ . Of course, eventually we need to consider this since we have a finite  $\lambda_{max} \ll \infty$ .

For now let us just evaluate the integral

$$\begin{aligned} \|\mathbf{W}\|^2 &= (\alpha - 1) \int_{\lambda_{min}}^{\lambda_{max}} \lambda \rho(\lambda) d\lambda \\ &= (\alpha - 1) \int_{\lambda_{min}}^{\lambda_{max}} \lambda^{\alpha-1} d\lambda \\ &= \frac{\alpha - 1}{2 - \alpha} [\lambda^{2-\alpha}]_{\lambda_{min}}^{\lambda_{max}} \end{aligned}$$

Since  $\lambda_{min} \sim 0$ , we have

$$\|\mathbf{W}\|_F^2 \approx \frac{\alpha - 1}{2 - \alpha} \lambda_{max}^{2-\alpha}$$

Taking the log of both sides now gives an expression for the log Norm (squared)

$$\log \|\mathbf{W}\|_F^2 \approx (2 - \alpha) \log \lambda_{max} + \log K_\alpha$$

where  $K_\alpha = \frac{\alpha - 1}{2 - \alpha}$  is a normalization term that does not depend on  $\lambda_{max}$ .

**Power Law - Norm Relation** [michael: Why is the sign wrong ?!]

Let us first write

$$\log \|\mathbf{W}\|_F^2 \approx (-\alpha) \log \lambda_{max} + 2 \log \lambda_{max} + \log K_\alpha$$

Notice that if we divide the log Norm by the log max eigenvalue, we get the the *Stable Rank*, but with the numerator and denominator in log units. We define this ratio as the

*Log-Units Stable Rank*:

$$\mathcal{S}_R^{log} := \frac{\log \|\mathbf{W}\|_F}{\log \lambda_{max}}$$

Our simple derivation suggests that this ratio is linear in  $\alpha$ :

$$\mathcal{S}_R^{log} \sim B\alpha + 2 + \dots$$

Notice that when  $\alpha < 2$ , then  $\lambda_{max}^{2-\alpha}$  is large, and the relation is dominated by  $\alpha$ . But when  $\alpha > 2$ , then  $\lambda_{max}^{2-\alpha}$  is small, and the Log-Units Stable Rank is  $\mathcal{S}_R^{log} \sim 2$ .

[michael: combine into 1 equation...and why is  $B > 0$  ?]

$$\mathcal{S}_R^{log} \approx B\alpha \quad \alpha < 2$$

$$\mathcal{S}_R^{log} \approx 2.x \quad \alpha > 2$$

We can test this relation between the Power Law exponent and the Log Frobenius Norm numerically. We generate a large number of random Heavy Tailed random matrices  $\mathbf{W}^{rand}(\mu, M)$ , with different

number of eigenvalues  $M$  (with aspect ratio  $Q = 1$ ), and drawn from a Pareto distributions with exponents  $\mu \in [0.5, 5]$

$$\Pr[W_{i,j}^{rand}] \sim \frac{1}{x^{1+\mu}}$$

We fit the ESD of each  $\mathbf{W}^{rand}$  to a power law using the method of Clauset et. al. to obtain the exponent  $\alpha$ . We then examine the empirical relation between the Log-Units Stable Rank  $\mathcal{S}_R^{log}$  and the ESD Power Law exponent  $\alpha$

$$\mathcal{S}_R^{log} \text{ vs. } \alpha$$

[michael: or is this better:

$$\frac{\log \|\mathbf{W}\|_F}{\log \lambda_{max}} \text{ vs. } (\alpha)$$

]

Figure ? plots the data for the *Power Law-Norm* relation

Figure 1: Numerical test of the Power Law - Norm Relation for random Heavy Tailed matrices

[charlesG: Describe here.

The numerical results for the the Power Law-Norm relation shows several interesting features:

First, as  $\alpha$  increases, the Log-units Stable Rank increases. Then it

- is very clear for  $\alpha < 2$
- saturates for  $\alpha > 2$  for large  $M$
- extends beyond  $\alpha > 2$  because of finite size effects

]

[charlesG: I am not sure why the slope is not negative...the eigenvalues are VERY LARGE, and  $\log \lambda_{max} \approx 3 - 5$  so this just is OFF. Are we missing something in the derivation, like the fact that the norm squared has to be positive ? HELP]

**Defining the Layer Weight Matrices** [charles: Here we describe how we exact the matrices. We have not done this yet for convolutional layers—thats *another* paper]

$$\text{Linear Layer: } \log \|\mathbf{W}_l\|^2 \rightarrow b_l \alpha_l$$

For the Conv2D layers, we relate the 'Norm' of the 4-index Tensor  $\mathbf{W}_l$  to the sum of the integrals of the  $n = c \times d$  ESDs for each feature map, giving

$$\text{Conv2D Layer: } \log \|\mathbf{W}_l\|^2 \rightarrow \sum_i b_{i,l} \alpha_{i,l}$$

So in the expression for the product norm for  $\log \mathcal{C}$ , let us replace each  $\log \|\mathbf{W}_l\|$  for layer  $l$  with the sum of the power law exponents  $\alpha_{i,l}$  for the  $n_l$   $\mathbf{W}_{l,i}$  layer matrices, and take the average over all  $N_\alpha$  matrices. This lets us relate the product norm complexity metric to the weighted average of power law exponents

where

$$\hat{\alpha} := \frac{1}{N_\alpha} \sum_{i,l} b_{i,l} \alpha_{i,l}$$

We can now use  $\hat{\alpha}$ , or, equivalently,  $2\langle \log \|\mathbf{W}\| \rangle$  to analyze numerous pre-trained DNNs...and the results are indeed surprising.

I HAVE PLOTS FOR BOTH ! Which should we display ?

[michael: How to resolve normalization issue ?

We need a normalizer  $K$  that

$$K \int_0^{\lambda_{max}} \rho(\lambda) d\lambda = 1$$

and we know that our final expression is off by a sign in alpha

So we need a normalizer that has

$$K \sim \lambda_{max}^{2\alpha}$$

or maybe

$$K \sim \lambda_{max}^{2\alpha-2}$$

But also know that

$$\int_0^{\lambda_{max}} \rho(\lambda) d\lambda = \frac{1}{1-\alpha} \lambda_{max}^{1-\alpha}$$

which suggests that

$$K \frac{1}{1-\alpha} \lambda_{max}^{1-\alpha} = 1$$

and that we might write  $K$

$$K = (\alpha - 1) \lambda_{max}^{1-\alpha}$$

notice we use  $(\alpha - 1)$  and not  $(1 - \alpha)$  since  $\alpha > 1$ ...but I think we need something like

$$K \left[ \frac{1}{1 - \alpha} \lambda_{max}^{1-\alpha} \right]^2 = 1$$

giving

$$K = (1 - \alpha)^2 \lambda_{max}^{2\alpha-2}$$

But this gives the wrong expression for the integral

$$K \int_0^{\lambda_{max}} \rho(\lambda) d\lambda = 1$$

and only works for

$$K \left[ \int_0^{\lambda_{max}} \rho(\lambda) d\lambda \right]^2 = 1$$

and I don't know how to stick it back into the formula for the Trace to get right result ]  
[charles: I actually think most of this is wrong and that we need to be more clever For example, see <http://www-personal.umich.edu/~mejncourses/2006/cmplxsys899/powerlaws.pdf>

where they derive an expression for the expected max eigenvalue  $\langle \lambda_{max} \rangle$  in terms of  $M$ , for an non-truncated power law

$$\langle \lambda_{max} \rangle \sim M^{1/(\alpha-1)}$$

So we would have ( $\alpha > 1$ )

$$\log \langle \lambda_{max} \rangle \sim \frac{1}{\alpha - 1} \log M$$

or

$$(\alpha - 1) \log \langle \lambda_{max} \rangle \sim \log M$$

Now maybe in our case there is some way to add in information about the norm of  $W$  on the R.H.S. where the  $\log M$  term arises ?

]

### 3 EMPIRICAL RESULTS ON PRETRAINED DNNs

**VGG and VGG BN Models** We start by looking at the VGG class of models, including VGG11, VGG13, VGG16, and VGG19, and their counterparts with Batch Normalization, VGG11\_BN, VGG13\_BN, VGG16\_BN and VGG19\_BN. Figure 2

## 4 DISCUSSION

We have presented a *Unsupervised* metric which predicts the trends in the test accuracies of a trained deep neural network—without peeking at the test data. This complexity metric  $\hat{\alpha}$  is a weighted average of the power law exponents  $\alpha$  for each layer weight matrix, where  $\alpha$  is defined in our Theory of Heavy Tailed Implicit Regularization. We prove that this new complexity metric  $\hat{\alpha}$  is equivalent to the average log of the Frobenius norm of the layer weight matrices,  $\langle \log \|\mathbf{W}\| \rangle$ , which is much easier to compute.

We examine several commonly available, production quality, pretrained DNNs by plotting the average complexity metric  $\langle \log \|\mathbf{W}\| \rangle$  vs the reported (Top1) test accuracies. This covers classes of DNN architectures including the VGG models, ResNet, DenseNet, etc. In nearly every class, the smaller average complexity, the better the test accuracy.

[charlesG: We can do BOTH log Norm and Weighted Alpha...which ? ]

The method is consistent with both recent theoretical results by Hidary and Poggio, but the approach and the intent is a bit different. Unlike their result, our approach does not require modifying the loss function. Moreover, they seek a *worst case* complexity bound. We seek *average case* metrics that can be used in production to guide the development of better DNNs.

But most importantly, we can apply these complexity metrics *across related DNN architectures*. This is in stark contrast to the standard practice in machine learning. The equivalent notion would be to compare margins across SVMs applied to the same data, but with different Kernels. One loose interpretation is that a set of related DNN models (i.e. VGG11, VGG13, ...) is analogous to a single, very complicated Kernel, and that the hierarchy of architectures is analogous to the hierarchy of hypothesis spaces in VC theory. [charlesG: more here ? like this ?]

We believe this result will have large applications in hyperparameter fine tuning DNNs. Because we do not need to peek at the test data, it may prevent information from leaking from the test set into the model, thereby helping to prevent overtraining and making finetuned DNNs more robust.

This work also leads to a much harder theoretical question; is it possible to determine if a DNN is overtrained without peeking at the test data ?
